NOTICE TO READERS
The information in this technical handbook is generally descriptive only, and is not intended to make or imply any guarantee or warranty with respect to any cells and batteries. Cell and battery designs are subject to modification without prior notice. Performance of a battery should be based on its corresponding data sheet and product specification.
1 Introduction

1.1 Overview

1.1.1 Chemistry - the early days
Nickel metal-hydride (NiMH) technology has been used commercially since the early 1990’s, mainly with consumer applications. At the time, nickel cadmium (NiCd) was the mainstream technology to which NiMHs was often compared. Even in the early days, it was recognised that NiMH batteries not only able to achieve higher energy density than NiCds, also more environmentally friendly.

Since both systems employed 1.2V in nominal voltage and also share many performance characteristics, it was relatively easy to adapt NiCd applications for use with NiMH.

Subtle differences between the two chemical systems made direct substitution of NiCd by NiMH a difficult process. Differences in the charging curve profiles meant that modification was required for fast charging of NiMH batteries. The early NiMH batteries were generally considered weaker in charge retention performance, and were not deemed suitable for high-drain applications.

1.1.2 Well established product series
Over the years, there have been significant improvements in NiMH technology, with most of the early weaknesses now eliminated. NiMH batteries of today outperform NiCds in many areas, including continued advances in energy density. There are now NiMH batteries that have twice the energy density of similar-sized NiCds, and many new applications are designed specifically for NiMH battery use, including: cellular phones, camcorders, audio-visual equipment, toys, laptop computer and personal care products.

GP NiMH rechargeable batteries had long been established as a well-known choice that offers performance, reliability and value. We have expanded our NiMH product range into various series to custom fit various application requirements.

-- the ever popular standard series is designed for a wide variety of general applications, including toys, personal audio equipment, cameras and cordless phones.

1.2 NiMH Chemistry

1.2.1 Principle
As with any other rechargeable battery system, NiMH batteries operate on the principle that electrochemical reactions at each of the electrodes are reversible; this enables energy to be stored during charging and released during discharging.

1.2.2 Positive electrode chemistry
The reaction that occurs at the positive electrode of a NiMH battery is the same as that for its NiCd counterpart:

\[
\text{Ni(OH)}_2 + \text{OH}^- \rightarrow \text{NiO(OH)} + \text{H}_2\text{O} + e^- \quad \text{(during discharging)}
\]

\[
\text{Ni(OH)}_2 + \text{H}_2\text{O} + e^- \rightarrow \text{Ni(OH)}_2 + \text{OH}^- \quad \text{(during charging)}
\]

-- for capacity demanding applications, our high capacity series is available. This has been achieved through revolutionary designs in mechanical construction and new chemical formulation.

-- the high-temperature series is designed for applications whereby the battery may encounter elevated temperature during operation. Special designs ensure that the battery performance is stable and reliable under adverse environmental conditions. Emergency lighting is one of such applications best served by the high-temperature series.

-- the high-drain series is expertly customized for powerful delivery of electrical energy on demand. Power tools and electronic bicycles are among some of the applications that excel with our high-drain series as power sources.

1.2.3 Negative electrode chemistry
The active material in the negative electrode is an alloy, which can reversibly absorb and release hydrogen atoms. There is no free hydrogen gas involved in the charging and discharging of the electrode.

There are two basic types of hydrogen-storage alloys available for NiMH batteries. One type consists of transition metals, such as titanium and zirconium, often referred to as the AB_5 alloys. The second type is made up of the rare-earth elements such as lanthanum, known as the AB_7 alloys.

The following reactions occur during the charge and discharge operations:

\[
\text{MH} + \text{OH}^- \rightarrow \text{M} + \text{H}_2\text{O} + e^- \quad \text{(during discharging)}
\]

\[
\text{MH} + \text{H}_2\text{O} + e^- \rightarrow \text{M} + \text{OH}^- \quad \text{(during charging)}
\]

In the equations above, M represents the hydrogen-storage alloy. MH is formed when hydrogen atoms, from the electrolysis of water, are absorbed by the alloy M. Upon discharge, the hydrogen atom is released and converted back to water.

1.2.4 Overall reaction
Combining the equations in 1.2.2 and 1.2.3 reveals the overall cell equation.

\[
\text{Ni(OH)}_2 + \text{M} + \text{O}_2 \rightarrow \text{NiOOH} + \text{MH}
\]

\[
\text{discharging}
\]

1.2.5 Cell pressure management - charge reserve
The overall reaction schematically depicts a simple transfer of H atom between Ni(OH)_2 and M, depending on whether the cell is being charged or discharged.

\[
2\text{M} + 2\text{H}_2\text{O} + 2e^- \rightarrow 2\text{MH} + 2\text{OH}^-
\]

For hermetically sealed batteries, the following mechanisms:

\[
\text{4M} + \text{O}_2 \rightarrow 4\text{M} + 2\text{H}_2\text{O}
\]

\[
\text{O}_2 + 2\text{H}_2\text{O} + 4e^- \rightarrow 4\text{OH}^-\quad \text{discharging}
\]

The first equation represents a direct combination of the O_2 gas with MH, which is present in significant amounts at the negative electrode of a fully charged battery. The second equation is a reverse of the electrolysis reaction that originally generated the O_2 at the positive electrode. The end result of these two equations is that gaseous O_2 is reabsorbed by the negative electrode, thereby preventing unacceptably high internal pressure during the charging reactions.

In addition, most hermetically sealed rechargeable batteries are equipped with resealable or non-resealable (one time) venting systems, which safely release any internal pressure that might have built up when the batteries were exposed to unexpectedly severe conditions of operations.

However, due to the excess capacity (charge-reserve) in the negative electrode, the corresponding electrolysis product of hydrogen will be prevented from forming. Instead, the oxygen gas from the positive electrode diffuses to the negative electrode and is consumed in the oxygen recombinant reaction.

The oxygen recombinant at the negative electrode occurs simultaneously, via two reaction mechanisms:

\[
4\text{OH}^- \rightarrow \text{O}_2(g) + 2\text{H}_2\text{O} + 4e^-\quad \text{charging}
\]

\[
\text{4OH}^- \rightarrow \text{O}_2 + 2\text{H}_2\text{O} + 4e^-\quad \text{discharging}
\]
1.2.6 Minimising damage during deep discharge - discharge reserve

In the event of deep discharge, depreciation of battery performance may occur. To minimise the possibility of damage, the excess capacity in the negative electrode also acts as discharge-reserve, preventing the negative electrode from being oxidised in the event that the battery is deeply discharged.

The relationship between the useful capacity, charge reserve and discharge reserve is shown in the following schematic representation.

2 Performance Characteristics

2.1 Charging Characteristics

2.1.1 Overview
The charging process aims to restore the battery for use by charging the battery externally. The charge voltage is affected by current, ambient temperature and time. At the same ambient temperature, the basic principle is: the higher the current, the higher the charge voltage as a result of increased over-potential at both electrodes.

When almost fully charged, peak voltage is attained. However, if the battery is overcharged, a slight decrease in voltage occurs; this arises from a temperature increase due to the exothermic oxygen recombination reaction. As a result, internal pressure builds up and heat is generated during overcharging. At a low charge rate (such as 0.1C or below), equilibrium pressure can be attained through a balanced electrode design. In addition, heat generated during overcharging is dissipated into the environment. The battery temperature is also affected by the current and ambient temperature.

2.1.2 Charging efficiency
In general, it is more efficient to charge the battery at or below room temperature, since the chemicals of both positive and negative electrodes are more stable at lower temperatures - resulting in higher discharge capacity. The charging efficiency of standard series NiMH batteries drops rapidly when the ambient temperature exceeds 40°C. Furthermore, the decrease is more pronounced at low charging rates, since the return of electrode chemicals to their lower charge state is more evident. The high temperature series, on the other hand, allow applications of trickle charge at temperatures as high as 70°C. The technology is a result of dedicated research by GP to enhance the stability of battery materials at high temperatures.

2.2 Discharge Characteristics

2.2.1 Overview
The nominal discharge voltage of a NiMH battery is 1.2V at 0.2C discharge, which is almost identical to that of a NiCd battery. The discharge time of a NiMH cell is almost 1.5 times that of the NiCd cell of same size, due to the high energy density of NiMH batteries.

2.2.2 Discharge voltage
The discharge voltage is affected by current and ambient temperature. Like NiCd batteries, the discharge voltage of NiMH batteries is depressed at lower temperatures. This is because both NiCd and NiMH batteries have an aqueous electrolyte system, resulting in decreased ionic mobility at lower temperatures. At higher currents, the discharge voltage of NiMH batteries is depressed, since the metal-hydride electrode is more polarised.

Previously, most NiMH cell manufacturers recommended 3C as the maximum discharge current; otherwise the discharge voltage would have simply been too low for many applications. As a result of advancements in NiMH battery technology, the discharge current achieved by some of the latest NiMH batteries can now achieve as high as 10C.

2.2.3 Discharge capacity
The discharge capacity is defined as "the product of discharge current and discharge time when the battery reaches the end discharge voltage." The nominal discharge capacity is rated at 0.2C to an end voltage of 1V after charging at 0.1C for 14 - 16 hours.

The discharge capacity is also affected by discharge current and ambient temperature. Capacity decreases with decreased temperature due to lower reactivity of the active materials and higher internal impedance. At a higher discharge current, the usable capacity is reduced due to larger IR drop, and also because the battery voltage drops off more rapidly to end voltage.

2.2.4 Polarity reversal during over-discharge
Most real-life applications employ multi-cell, series-connected batteries. When discharging, the lowest capacity cell will be the first to experience a voltage drop. If the battery discharge continues, this unit cell will be driven into an over-discharged condition. When the cell voltage drops below 0V, its polarity is effectively reversed. The cell reaction, at different stages, is illustrated below:

Stage 1: Initially, both positive and negative electrodes, as well as the discharge voltage are normal.

Stage 2: The active material on the positive electrode has been completely discharged and evolution of hydrogen occurs. Cell pressure builds up, although part of the gas can be absorbed by the negative metal alloy electrode. Since the battery is designed with excess negative capacity (discharge reserve), the discharge continues; discharge voltage is around -0.2V to -0.4V.

Stage 3: The active material on both electrodes has been depleted and oxygen generation starts at the negative electrode. Formation of gases at both electrodes leads to high internal cell pressure and opening of the safety vent, resulting in deterioration of the cell performance if this scenario occurs repeatedly.
The battery loses its energy during storage, even with correspondingly high temperatures. The recommended humidity level for battery storage is a maximum of 60% RH.

2.3 Storage Characteristics

2.3.1 Overview

The battery loses its energy during storage, even without loading. The energy is lost through small, self-discharge currents inside the battery, as explained below:

a. Decomposition of nickel hydroxide in the positive electrode:
The nickel hydroxide is relatively unstable in a charged state and tends to return to a discharge state with the slow released of oxygen. The released oxygen then reacts with the hydrogen in the negative electrode, thus establishing an internal discharge path. The reaction rate increases with higher temperatures.

b. Release of hydrogen from the negative electrode:
There is a very low hydrogen equilibrium pressure for the metal-hydride electrode; such hydrogen reacts with the positive electrode. After consumption of the hydrogen, it is replenished from the metal-hydride electrode and the reaction continues at a steady rate. The reaction rate depends on the hydrogen equilibrium pressure, which is higher at increased temperatures.

c. Side reactions through impurities:
Some of the impurities can be oxidised in the positive electrode when it migrates to the negative electrode, where it reverts to its original form. The shuttle reaction of the impurities dissipates the battery’s power during storage. The reaction rate is also temperature-dependent.

2.3.2 Storage temperature

As already mentioned, the self-discharge reaction rate increases with higher temperatures. Prolonged storage of the battery at elevated temperatures will result in the battery material deteriorating faster; leakage performance will also deteriorate, resulting in a reduced battery lifetime. It is recommended that, for long storage, batteries should be kept at room temperature or below.

2.3.3 Storage time

As the battery loses energy during storage, the voltage also drops. In general, the battery capacity loss due to self-discharge during storage can be recovered by recharging. If the battery is stored for over six months it is advisable to cycle the battery several times to resume the battery capacity.

2.3.4 Storage humidity

Leakage and rusting of metal parts are accelerated in high humidity environments, especially those with over 8 cells in series, less by one.

2.4 Cycle Life

2.4.1 Overview

Cycle life is the number of charges and discharges a battery can achieve before the discharge capacity (0.2C) drops to 60% of the nominal capacity per IEC 61951-2 or other guaranteed value per GP specifications. Cycle life is affected by ambient temperature, as well as depth of charge and discharge. A common phenomenon to the NiMH battery is that the impedance increases upon cycling due to electrolyte dry-out, especially at the end of the cycle life. During overcharging, gases form and pressure builds up inside the battery; trace amounts of gas escape through the seal or vent hole, leading to moisture loss and separator dry-out. Actually, NiMH battery can attain 500-1000 cycles with cycling conditions of 0.1C charge/0.2C discharge.

2.4.2 Ambient temperature

It is recommended to cycle the battery at room temperature. At higher temperatures, the electrodes as well as the separator material deteriorate much faster, thus shortening the cycle life. At lower temperatures, the rate of oxygen recombination during overcharge is slow, and may risk opening the vent leading to pre-mature electrolyte dry-out.

2.4.3 Overcharge

The cycle life of the battery is sensitive to the amount of overcharge at high charge rate. The amount of overcharge affects cell temperature and oxygen pressure inside the battery. Both factors deteriorate the metal-hydride electrode through oxidation and thus the cycle life shortens. For that reason the cycle life is affected by various charge cut-off methods.

2.4.4 Deep discharge

The cycle life is also affected by the depth of discharge. The number of charge/discharge cycles will decrease if the battery is repeatedly subjected to deep discharging below 1V, or to a status of polarity reversal. Considerably more cycle numbers can be obtained if the battery is cycled under shallower cycling conditions.

2.5 Safety

If pressure inside the battery rises as a result of improper use, such as overcharge, short circuit, or reverse charging, a resealable safety vent will function to release the pressure, thus protecting the battery from bursting.

2.6 Characteristics of Various Series

GP NiMH rechargeable batteries had long been established as a well-known choice that offers performance, reliability and value. In order to widen
its field of applications and extend its full advantages, we have expanded our NiMH product range into various series to custom fit various application requirements.

2.6.1 Standard Series
Our standard series is designed for a wide variety of general applications, which features a combination of superior positive and negative electrode, allowing us to provide the highest levels of capacity and quality for each size. These NiMH batteries also feature excellent discharge performance, low internal resistance and reliable characteristics across a wide range of temperatures, and they have been carefully designed for safety and reliability. Ranging from compact sizes to large sizes, the standard series is available in a wide selection of discharge capacities based on the standard sizes specified in IEC61951-2.

2.6.2 High Drain Series
Our high drain series is expertly customized for powerful delivery of electrical energy on demand. It was developed through an integration of our comprehensive NiMH battery technology. Improvements in the positive and negative electrode technology, and in the current collecting system have further lowered the internal resistance and greatly enhance the 10C discharge characteristics of the high drain series batteries.

- Excellent high current discharge characteristics
  It is designed to meet the need for high current discharge, such as for power tools, and can deliver a high current exceeding 10C.

- Reliable, long cycle life
  In addition to excellent high rate discharge performance, high drain series batteries also provide hundreds of charge/discharge cycles, showing reliable cycle life characteristics.

2.6.3 High Temperature Series
With standard series NiMH batteries, the smaller the charging current and the higher the charging temperature, the more difficult it is for the battery to charge. However, for applications in which the batteries are charged continuously by a small current under relatively high temperature conditions such as emergency lights, there is a need for superior high temperature trickle charge performance. By combining GP’s technology in electrodes and electrolyte, high temperature series NiMH batteries are far superior to the standard series NiMH batteries for use in high temperature trickle charge applications. Furthermore, the use of a special separator provides stable trickle charge life characteristics.

- Performance, low internal resistance and reliable characteristics
  of secondary battery applications. Since different battery systems have their own characteristics and applications have their own integrated electrical input/output requirements, it is vital to select a charging method that suits both the battery system and the application. Improper charging will lead to poor battery performance or failure of the application.

3 Charging Method

3.1 Overview
One crucial difference between the primary and secondary battery is the ability to restore energy after discharging. This restoration of energy is therefore a very important area to be considered in secondary battery applications. Since different battery systems have their own characteristics and applications, the selection of a charging method that suits both the battery system and the application is crucial.

3.2 Charging Method
Like NiCd, the main concern in charging a NiMH battery is the build-up of temperature and internal pressure due to high overcharge rates. As previously mentioned, the cell design applies the concept of oxygen recombination in lowering the battery's internal oxygen level during standard charging. However, if the cell is subjected to severe charging conditions (such as overcharging at a current rate over 1C), the rate of oxygen evolution from the positive electrode increases rapidly, exceeding the recombination reaction rate. As the oxygen recombination reaction is exothermic, this results in excessive oxygen pressure and increased temperature. The excessive pressure will then be released through the safety vent causing a reduction in the cell electrolyte; the excessive heat will eventually degrade the cell's internal contents. These two factors are considered to be the major limitations to the battery's service life. For this reason, charge control is very important in battery charging. GP NiMH cylindrical cells are designed to be able to charge up to 1C rate. For applications that require higher charging rates, please contact GP.

In secondary battery charging the two most commonly used methods are constant voltage charging and constant current charging. As with the NiCd system, constant voltage charging is not recommended for NiMH, due to thermal runaway under overcharging conditions. As mentioned earlier, the heat generated by the overcharge current can cause a significant rise in battery temperature, which will cause a drop in the battery charging voltage. In constant voltage charging, the overcharge current is determined by the potential difference between the power source and the battery charging voltage. The increased difference between the power source and the battery charging voltage, due to the temperature rise, will also augment the overcharge current. This increase in the overcharge current will lead to a further increase in cell temperature. This positive feedback cycle of cell temperature and overcharge current will not run down until the battery fails or until the current limit of the charger is reached. For this reason, constant voltage charging should not be used in charging NiMH batteries, and charge control should be employed if this method cannot be avoided.

3.2.1 Constant current charging
The advantages of the constant current charging method include high charging efficiency, flexibility, and position control of input capacity.

3.2.2 Fast charging
GP NiMH batteries use constant current charging as the basis of the charging method. Depending on different operational requirements, constant current charging can be further classified according to the charging rate. Charging at a current rate of 0.5C to 1C, or higher (up to 3C), is considered fast charging. As explained earlier, if the charging current is too high (1C or above), the cell internal pressure and temperature will rise at the end, resulting in degraded cell performance and electrolyte leakage.

3.2.3 Charge control
Various methods are recommended to help control charging, so as to prevent gas pressure and temperature build-up due to overcharging. Proper charge control will provide a longer battery service life.
4 Battery Assembly

4.1 Connections Between Cells

The resistance spot-welding method is to be used when NiMH cells are connected in a series, to avoid an excessive increase in cell temperature, which would occur if soldered directly. Leads used for cell connections should be nickel-plated or pure nickel measuring 0.1mm to 0.4mm in thickness and 3mm to 6mm in width.

Temperature of NiMH cells rises when the charge gets close to completion. Temperature increase is greater for a battery pack than for a single cell, due to the fact that the pack does not really allow for the dissipation of heat. The problem is further exacerbated when the pack is enclosed in a plastic case. Air ventilation should be provided in the plastic case of batteries – to allow for egress of any gases that may result from activation of the safety vent of cells after abuse.

4.2 Thermal Protection for Battery Packs

Battery packs intended for fast charging methods should have a thermal protection device. A thermistor sensing the temperature inside the pack should be employed. It is also desirable to have a thermostat/polyswitch and a thermal fuse installed in the battery pack to protect it from abnormal rises in temperature and external short-circuiting. Locations for safety devices in battery pack assembly are shown in the following diagrams.

3.2.5 Trickle Charging

In most applications - where cells and batteries need to be in a fully charged condition - maintaining a trickle charge current to compensate for the loss of capacity (due to self-discharge) is recommended. The suggested trickle charge current to be used is 0.05C to 0.1C.

3.2.6 Charging Temperature

As ambient temperature affects charging efficiency and cell reliability, it is important to select a suitable temperature for optimising charging performances. Generally speaking, a temperature within 10°C to 45°C will yield the highest efficiency, which begins to drop at or above 45°C. Conversely, repeated charging at less than 0°C may cause cell internal pressure build-up, resulting in electrolyte leakage as in high temperature conditions. For these reasons, GP NiMH batteries can be charged at temperatures of 0°C to 45°C under standard charging conditions, but preferably at 10°C to 45°C under fast charging conditions.

4.3 Standard Charge

Apart from fast charging, GP NiMH batteries can also be charged at a lower current rate of 0.1C. As this charging method is less severe, charge termination at 160% nominal capacity input is recommended (to help avoid extended overcharging of the battery). Also, in some applications where overcharging is necessary, GP NiMH batteries can endure 0.1C continuous charging for about one year.

3.2.4 Trickle Charging

In most applications, cells and batteries need to be in a fully charged condition - maintaining a trickle charge current to compensate for the loss of capacity (due to self-discharge) is recommended. The suggested trickle charge current to be used is 0.05C to 0.1C.

b) -dV control

Detecting the value of the voltage drop after reaching peak volting is the most commonly used charge control method in fast charging GP NiMH batteries. A -dV value of 0-5mV/cell is recommended when fast charging GP NiMH batteries, while a -dV value of 2mV/cell is found to provide the best balance between charge termination and service life performance.

c) Charging time control (back up only)

An easier way to control fast charging of GP NiMH batteries is to control the elapsed time following commencement of charging. However, it is not recommended as the only cut-off method due to overcharging. A charging time equal to 105% of the cell nominal capacity is recommended.

d) Battery temperature control

As increased ambient and cell temperatures result in high cell internal pressure, it is highly recommended to have temperature control backup for safety and cell performance. When fast charging GP NiMH batteries, the cut-off temperature is recommended to be controlled at 45-50°C.

3.2.4 Standard Charge

Apart from fast charging, GP NiMH batteries can also be charged at a lower current rate of 0.1C. As this charging method is less severe, charge termination at 160% nominal capacity input is recommended (to help avoid extended overcharging of the battery). Also, in some applications where overcharging is necessary, GP NiMH batteries can endure 0.1C continuous charging for about one year.

Connector Type Specifications

GP Universal Plug - exclusively from GP, offers distinctive features unparalleled in the market.

Major Benefits
- Compatible with most cordless phone models (Interchangeable with Mitsumi, JST, Molex plugs etc.)
- Minimise inventory items
- User friendly

6 Proper Use and Handling

6.1 Restriction on Usage

Knowledge of battery maintenance is crucial to a working battery, helping to provide a longer period of operation. On the other hand, improper battery handling or maintenance may lead to unnecessary battery defects or problems, such as electrolyte leakage or cell bulging. In order to get the most out of using GP NiMH rechargeable cells, special care in the following areas should be considered:

6.1.1 Charging / discharging current

For fast charging GP NiMH batteries, the current rate should be 0.5C to 1C. Trickle charging, which is common in various applications (such as memory backup), requires a current charging range of 0.05C to 0.1C to maintain the long-term standby power of the battery. In addition, GP NiMH batteries can be trickle-charged at 0.1C continuously for one year without leakage or explosions. Charging current rates higher than 1C are generally not recommended. However charging with pulses higher than 1C is not uncommon in some applications. Please contact authorised GP personnel to determine the applicability of special charging schemes not mentioned in GP product specifications.

Special attention should be paid to the charge termination method, which is a critical element in providing an optimised cycle life, yet one which is easily overlooked. Several charging cut-off mechanisms with related parameters can be considered:

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Negative delta voltage</td>
<td>0-5mV</td>
</tr>
<tr>
<td>dT/dt</td>
<td>0.8°C/minute (0.5C to 0.9C)</td>
</tr>
<tr>
<td></td>
<td>0.8-1°C/minute (1C)</td>
</tr>
<tr>
<td>Temperature control</td>
<td>45-50°C</td>
</tr>
<tr>
<td>Timer control</td>
<td>105%</td>
</tr>
</tbody>
</table>

These charging cut-off mechanisms can be incorporated into the application – either together or individually, with the choice of method depending largely on the charging profile of the application. To avoid unnecessary battery problems, which might look like quality issues, please contact authorized GP personnel for implementing the appropriate charging cut-off method.

A wide range of required discharge current rates will be encountered in different applications, and GP has a variety of battery types for specialised use. Apart from the standard series for general applications, high temperature and high drain series are specially designed for applications in high ambient temperatures and discharge current rates respectively. The maximum discharge current recommended for batteries of standard series is generally 3C. However, there are situations where higher currents of shorter duration are permissible.

6.1.2 Reverse charging

Reverse charging is one of the battery misuses that can appear to be a battery defect, if the positive and negative polarities are reversed when charging, the battery might bulge due to internal gassing. Electrolyte leakage consequently results due to venting at the safety valve, which leads to a decrease in capacity. Caution has to be exercised to avoid such misuse.

6.1.3 Parallel charging

Parallel charging is generally not recommended, please consult authorized GP personnel for possible exceptions to connecting the batteries in parallel charging.

6.1.4 Charging / discharging temperature

It is important to understand how ambient temperature affects the charging and discharging of batteries, especially for obtaining maximum efficiency in conditions that exceed room temperature. GP recommends the following temperature range.
6.2 Precautions for Designing Application Devices

6.2.1 Battery compartment
Bear in mind that there is always a chance of battery abuse, where internal gassing is highly probable; and as a result, the gas will be released through cell venting. However, generation of hydrogen gases from overcharging is particularly dangerous when mixed with oxygen. Caution should be focused on the ventilation of battery compartments. Airtight battery compartments are strongly discouraged. Ventilation should be provided in the plastic case of batteries, otherwise oxygen and hydrogen gas generated inside can cause explosion when exposed to fire sources such as motors or switches.

6.2.2 Charging / discharging / operating temperature
To optimise battery performance and service life, certain aspects related to charging, discharging and the operating temperature should be taken into careful consideration. A customer application questionnaire is provided in this technical handbook. Please provide as much information as possible. Alternatively, contact authorized GP personnel for advice and help with your application.

6.3 Methods of Use

6.3.1 Operation
Avoid combining used and fresh batteries, or batteries at different state-of-charge, which may lead to electrolyte leakage. Always cycle the battery several times to restore its capacity if the battery has been stored for an extended period of time.

6.3.2 Connection between battery and application devices
Be sure to connect the positive and negative battery terminals to the corresponding terminals of the application device, in order to prevent reverse charging.

6.4 Precautions in Battery Handling

- Never incinerate the battery.
- Never solder a battery directly.
- Avoid subjecting a battery to strong vibrations, pressure or impact.
- Never connect the battery terminals to the device without verifying the polarities.
- Never carry a battery with other metallic belongings to avoid short-circuiting.
- Never disassemble a battery.
- Never mix GP batteries with other battery brands or batteries of a different type.
- Never short together the positive and negative terminals of a battery with any metal.
- Never obstruct the safety vent, which is located near the positive terminal of the cylindrical/prismatic cell, and on the positive side of the button cell -indicated by a vent mark.
- Never alter the factory-configuration or remove/modify a component of a battery.
- Never charge/discharge a battery under conditions which are not within GP specifications, or without consulting authorized GP personnel on special applications.
- Never use other charger than specified to avoid possible heating, burning or rupture.
- Never leave a battery connected to a device for long periods without charging the battery, especially for devices that constantly drain standby current.
- If any abnormality or problem is found while using the battery, stop its use, and bring it to your local dealer.
- Never use cells or batteries for any other applications than specified, that may result in damage to the batteries and the appliances.

6.5 Battery Maintenance

6.5.1 Regular inspection
Periodic visual inspection of the battery is recommended. It is also advisable to store the battery at room temperature, with low humidity, when the battery is not expected to be used for a long period of time; the aim of which is to prevent cell leakage and rust.

6.5.2 Storage
Bear in mind that self-discharge has to be taken into consideration when storing a charged battery. The remaining battery capacity should be at least 50% after a month of storage at room temperature for a fully charged battery. High storage temperatures will accelerate the self-discharge, and reduce the remaining capacity.

In order to maintain battery performance when being stored for an extended period of time, cycling (charging and discharging) of the battery within a 6 to 9 month period is recommended. This procedure is recommended to maximize performance of the battery and prevent low OCV in long-term storage conditions. Failure to do so may result in a shorter battery life.

6.5.3 Battery disposal
Under normal conditions, when the battery has reached its end of life, it is advisable to properly insulate the positive and negative terminals of the battery prior to disposal. Please note that it is dangerous to dispose of the battery in fire, as it will lead to electrolyte spill-out and bursting of the battery.

Recycling of the battery is an important environmental issue nowadays. We recommend you contact your local government concerning the location of recycling sites, or enquire about local regulations on methods of disposal for NiMH batteries in your region.

6.5.4 Transportation
GP NiMH batteries should not be thought of as wet batteries (like traditional, non valve-regulated batteries). As a result, GP batteries can be shipped or transported in normal packaging without special hand.
7 Customer Application Questionnaire

I. Customer Information

<table>
<thead>
<tr>
<th>Component</th>
<th>Short circuit</th>
<th>Overcharge</th>
<th>Rating</th>
<th>Manufacturer</th>
<th>Model no.</th>
</tr>

IV. Approvals (GP internal use only)
Sales: ____________________________ Engineering: ____________________________
Glossary

Active Material
Chemicals that give rise to electro-chemical reactions, and which generate electrical energy in the battery.

Alkaline Electrolyte
An aqueous alkaline solution (such as potassium hydroxide) which provides a medium for the ionic conduction between the positive and negative electrodes of a cell.

Ampere-hour
Unit of capacity of a cell/battery. Capacity is defined as the product of the discharge rate and the discharge time.

Battery
Consists of one or more connected cells.

Capacity
The amount of electrical energy that can be supplied by a cell/battery - expressed in mAh, and in specified discharge conditions.

Cell
An electrochemical unit constituting positive and negative electrodes, separator, and electrolyte to provide electrical energy.

Cell Reversal
In reversal, the normal terminal polarities of a cell in a multiple cell battery are switched. Cell reversal normally occurs only if three of more unit cells are connected, and the battery is deeply discharged. Cell reversal is detrimental to performance, and should be avoided by proper selection of cut-off voltages during discharge.

Charge
The operation which inputs electrical energy to a cell/battery.

Charge Efficiency
A measurement of accumulated efficiency during the charging operation.

Charge Rate
The rate of current supplied to a cell/battery.

Charge Retention
The percentage of capacity remaining after a charged cell/battery has been stored for a period of time.

Closed-circuit Voltage
The voltage of the cell/battery with loading.

Constant Current Charging
Charging with a fixed current value.

C-Rate
Relative rate used in cell/battery, defined as the quotient of current (mA)/nominal capacity (mAh).

Cut-off Voltage
A set voltage that determines when the discharging of a cell/battery should end.

Cycle Life
The number of cycles a cell/battery can run under specific conditions, while still delivering specified minimum capacity.

Depth of Discharge
The percentage of the available capacity from a cell/battery during discharge.

Discharge
The operation which removes stored electrical energy from a cell/battery.

Discharge Rate
The rate of current drained from a cell/battery.

Electrode
A conducting plate containing active materials.

Exothermic Reaction
A chemical reaction which results in the release of heat energy as it proceeds.

Memory Effect
The phenomenon whereby the capacity of a cell may be temporarily decreased when it is repeatedly used in a shallow discharge pattern. Memory effects are erased when the cell is discharged to the normal cut-off voltage (e.g. 1.0V at the 0.2C discharge rate).

Negative Electrode
The electrode with negative potential. Current flows through the external circuit to this electrode during discharge.

Nominal Voltage
A general value to indicate the voltage of a battery in application.

Open-circuit Voltage
The voltage of the cell/battery without loading.

Overcharge
The continued charging of a cell/battery after it is fully charged.

Positive Electrode
The electrode with positive potential from which current flows through the external circuit to the negative electrode during discharge.

Rated Capacity
A nominal capacity available from a cell at specific discharge conditions.

Safety Vent
This is a device to release the gas when the internal pressure of the battery exceeds the pre-set value.

Self-discharge
The loss of capacity by a cell/battery during storage or in an unused condition. The rate of self-discharge is affected by ambient temperature.

Separator
The thin and porous membrane between the positive and negative electrodes to prevent short-circuit and hold the electrolyte.

Short Circuit
The direct connection of the positive electrode/terminal to the negative electrode/terminal of the battery.

Standard Charge
The normal charge rate used to charge a cell/battery in 16 hours. Normally 0.1C.

Thermal Fuse
A component assembled into batteries, which breaks the current when the temperature reaches a predetermined value.

Thermistor
A component with a negative temperature coefficient - built into batteries and/or used to detect the ambient and battery temperature.

Trickle Charge
A continuous and very low rate charging to keep a cell/battery on full capacity.
